ABSTRACT

Introduction:
Primitive mesenchymal tumors represent about 9%-15% of all hepatic tumors in children. Only about 150 cases have been reported in the literature so far. Hereby we report a case of Ruptured Embryonal Rhabdomyosarcoma.

Case Report:
A boy aged 16 years old with weight of 26 kg presented to us with sudden onset of abdominal pain and fever. Clinical examination revealed a tender hepatomegaly about 6 cm below Right costal margin. CECT abdomen revealed 15x 11x 9 cm heterogenous multi septated loculated mass lesion involving right lobe of liver involving segments 5,6,7,8. Diagnostic laparoscopy was done which showed a tumor occupying the entire right lobe of liver with no other deposits. The tumor capsule was seen ruptured on the right lateral side for which we did emergency right Hepatectomy. Weight of the specimen was 2.8 kilograms.

Histopathology revealed the lesion as Embryonal Rhabdomyosarcoma with co-existing mesenchymal hamartoma. Immunohistochemistry showed Vimentin and Desmin positive. Patient was on carboplatin and Ifosfamide chemotherapy. Patient expired on 30th postoperative day due to acute respiratory distress.

Conclusion:
Improved survival can be expected only if we detect the disease early. This case report will enlighten this type of rare tumor in young children and an early referral to the specialist.

Keywords: Primary Embryonal Rhabdomyosarcoma liver, Heterogenous mass in liver, Ruptured capsule, Right Hepatectomy.
INTRODUCTION

Primary liver tumors rank the third amongst the solid malignant tumors in children following Wilms tumor and Neuroblastoma. They account for 2% of total solid malignancies in paediatric cases [1]. Primitive mesenchymal tumors rank the fourth among the malignant tumors of paediatric age group following Hepatoblastoma, Infantile hemangio endothelioma and Hepatocellular carcinoma. Rhabdomyosarcoma is the malignant solid tumor arising from mesenchymal tissues which normally differentiates to form striated muscle. It is most common tumor in the age group less than 15 years. There are four types of Rhabdomyosarcoma- Pleomorphic, Embryonal, Alveolar and Botryoidal. The 5 year survival rate of localised disease is 80% and for metastatic disease- 5%

Primitive mesenchymal tumors represent about 9%-15% of all hepatic tumors in children. So far only 150 cases of rhabdomyosarcoma liver have been reported in the literature. Hereby we report a case of ruptured primary Embryonal Rhabdomyosarcoma of liver in a 16 year old male boy. Embryonal type of Rhabdomyosarcoma of liver is very rare and only 12 cases were reported in the literature so far.

CASE REPORT

16 years male with body weight of 26 kilograms presented to us with a mass in the right hypochondrium past 1 month with history of abdominal pain, fever with chills and rigors. He had no history of jaundice, weight loss or loss of appetite. On elaborating the history, the mass was present for the past 1 month and rapidly increased for the past 1 week with severe intolerable pain past 4 days. On clinical examination abdomen was soft and minimal guarding was present. A firm tender heptomegaly was present 6 cm below right costal margin. Surface found to be smooth and edges were rounded. CECT abdomen revealed 15x 11x 9 cm heterogenous multi septated loculated mass lesion involving right lobe of liver involving the segments 5,6,7,8 (Figure 1 and 2). Portal venous Doppler study showed displaced
and stretched right portal vein with normal flow. Laboratory investigations at the time of admission were Hemoglobin 8 gm/dl, Platelets- 4 lakhs/cubic mm, Blood sugar – 80 mg/dl, Blood urea- 22 mg/dl and Serum creatinine- 0.8 mg/dl. Two units of packed cells were transfused and the preoperative hemoglobin was 10 mg/dl. Tumor markers AFP and CA 19-9 were done. Alpha fetoprotein value was 4 ng/ml and CA 19-9 was found to 20 U/ml. Liver biopsy was not taken to avoid the risk of seedling of an operable tumor.

Diagnostic laparoscopy revealed a tumor occupying the segments 5,6,7,8 with ruptured capsule in the right lateral lobe of liver (Figure 3). There was no other peritoneal or omental mets. The left lobe of liver was found normal with other lesions. So we decided to proceed with right hepatectomy. The inflow control was done with Pringles manoeuvre. Parenchymal dissection was done with Harmonic scalpel and Kelly crush clamp technique (Figure 4, 5). The bleeding vessels from raw area in the left lobe were ligated with 3’0 Silk sutures. Specimen retrieved and complete haemostasis was achieved in the remnant liver raw area. Weight of the specimen was 2.8 kilograms (Figure 6).

Histopathology showed liver parenchyma with tumor composed of round to polyhedral and spindle shaped cells with bizarre nuclei, arranged in sheets and clusters with vague lobular pattern in some places. Tumor cells inhibit intracytoplasmic globules and multinucleate giant cells with atypical mitosis. Entrapped bile ductules are seen. Stroma shows extensive haemorrhagic areas with areas of necrosis. The above features are suggestive of Embryonal variety of Rhabdomyosarcoma probably coexisting with mesenchymal hamartoma (Figure 7a, 7b), resected margins were free of tumor.

IHC markers are positive for Vimentin showed focal positivity, Desmin showed diffuse strong positivity, CK 7 glands showed positivity. CD 34 was found negative. All these confirmed the diagnosis of Embryonal variety of Rhabdomyosarcoma. 1st cycle of chemotherapy started with Ifosfamide at 800 mg/day and Carboplatin at 300 mg/day.

Patient expired on 30th postoperative day suddenly because of respiratory distress and pleural effusion. Post mortem examination was not done.
DISCUSSION

Having an incidence of 9-15% in children, Hepatic Rhabdomyosarcoma liver needs a lot of experience to diagnose. Rhabdomyosarcoma was classified into four types—Pleomorphic, Alveolar, Embryonal and Botryoidal types. The predominant age of presentation are Pleomorphic type in male adults, Alveolar type in adolescents and young adults, Embryonal type in infants and children and Botryoidal type in young children. The different types of Rhabdomyosarcoma can be differentiated on the basis of histopathological appearance. The tumor cells are more elongated and less densely cellular in Embryonal type. In alveolar type the tumor cells tend to be smaller and rounder, often with a denser cellularity, and are so named because of their resemblance to the appearance of the small air sacs in the lungs (the "alveoli"). Rhabdomyosarcomas have very poor prognosis with 5 year survival rate of 80% for localised disease and 5% for metastatic disease.

These cases have a great challenge in treatment because of the rarity of the disease and absence of clinical trials and standard treatment guidelines. A lot of case reports published showed that most patients expired within 5 years of the diagnosis. Neoadjuvant chemotherapy was found to extend the survival of these patients [5]. Postoperative chemotherapy is advised for all patients. Various chemotherapy regimens are applied for these patients like Vinorelbine and Cyclophosphamide, Gemcitabine and Docetaxel, Rapamycin, Topotecan and Vincristine [3]. Our patient received Ifosfamide and carboplatin for 1 cycle, but unfortunately patient suddenly died of acute respiratory distress and pleural effusion.

With this case report we would like to stress the aggressive nature of this disease and the necessity for early detection of the disease. A multidisciplinary approach is needed in managing these patients as there is no protocol available. An extensive work-up is essential because these tumours have the potential to grow rapidly. PET CT scan may be of beneficial in these patients before surgery [2] and may help in diagnosing the metastasis before taking up for hepatectomy.
CONCLUSION

The poor prognosis and early death of most cases reported so far implies the necessity of early detection and evaluation of the disease. Surgical resection along with chemotherapy provides improved survival only if given in the early stage of the disease.
